

# Data Cleaning Cheat Sheet

Solavise Women in Data (SWID) Programme • Python & Pandas

Data cleaning is the process of fixing problems in your dataset before you analyse it. Messy data leads to wrong results. Always clean first!

## 1 First Look at Your Data

Run these lines before you do anything else. They tell you what your data looks like.

|                      |                        |
|----------------------|------------------------|
| See the first 5 rows | <code>df.head()</code> |
|----------------------|------------------------|

|                     |                        |
|---------------------|------------------------|
| See the last 5 rows | <code>df.tail()</code> |
|---------------------|------------------------|

|                        |                       |
|------------------------|-----------------------|
| Rows and columns count | <code>df.shape</code> |
|------------------------|-----------------------|

|              |                         |
|--------------|-------------------------|
| Column names | <code>df.columns</code> |
|--------------|-------------------------|

|                       |                        |
|-----------------------|------------------------|
| Column types and info | <code>df.info()</code> |
|-----------------------|------------------------|

|                          |                            |
|--------------------------|----------------------------|
| Stats for number columns | <code>df.describe()</code> |
|--------------------------|----------------------------|

|                             |                           |
|-----------------------------|---------------------------|
| See a random sample of rows | <code>df.sample(5)</code> |
|-----------------------------|---------------------------|

```
df.head() # first 5 rows
df.info() # column types + nulls
df.describe() # min, max, mean, etc.
```

## 2 Handling Missing Values

Missing values show up as NaN. You can find them, fill them, or remove them.

|                     |                                |
|---------------------|--------------------------------|
| Find missing values | <code>df.isnull().sum()</code> |
|---------------------|--------------------------------|

|                        |                          |
|------------------------|--------------------------|
| Drop rows with any NaN | <code>df.dropna()</code> |
|------------------------|--------------------------|

|                          |                                   |
|--------------------------|-----------------------------------|
| Drop only if ALL are NaN | <code>df.dropna(how='all')</code> |
|--------------------------|-----------------------------------|

|                             |                           |
|-----------------------------|---------------------------|
| Fill NaN with a fixed value | <code>df.fillna(0)</code> |
|-----------------------------|---------------------------|

|                           |                                                 |
|---------------------------|-------------------------------------------------|
| Fill NaN with column mean | <code>df['col'].fillna(df['col'].mean())</code> |
|---------------------------|-------------------------------------------------|

|                             |                                                   |
|-----------------------------|---------------------------------------------------|
| Fill NaN with column median | <code>df['col'].fillna(df['col'].median())</code> |
|-----------------------------|---------------------------------------------------|

|                               |                                                    |
|-------------------------------|----------------------------------------------------|
| Fill NaN with most common val | <code>df['col'].fillna(df['col'].mode()[0])</code> |
|-------------------------------|----------------------------------------------------|

**Tip:** Choose your fill strategy on purpose. Use the mean for numbers that are spread evenly. Use the median when there are outliers. Use the mode for categories or repeated values.

### 3 Removing Duplicates

Duplicate rows can make your results look bigger than they really are.

|                              |                                                 |
|------------------------------|-------------------------------------------------|
| Check for duplicates         | <code>df.duplicated().sum()</code>              |
| See duplicate rows           | <code>df[df.duplicated()]</code>                |
| Remove all duplicate rows    | <code>df.drop_duplicates()</code>               |
| Keep first occurrence only   | <code>df.drop_duplicates(keep='first')</code>   |
| Remove duplicates in one col | <code>df.drop_duplicates(subset=['col'])</code> |

```
# Remove duplicates and save result
df = df.drop_duplicates()
print(df.shape) # check new size
```

### 5 Cleaning Text

Text data is often messy. Extra spaces, mixed letter cases, and typos are very common.

|                                |                                               |
|--------------------------------|-----------------------------------------------|
| Remove extra spaces            | <code>df['col'].str.strip()</code>            |
| Make all text lowercase        | <code>df['col'].str.lower()</code>            |
| Make all text uppercase        | <code>df['col'].str.upper()</code>            |
| Capitalise each word           | <code>df['col'].str.title()</code>            |
| Replace one value with another | <code>df['col'].replace('old', 'new')</code>  |
| Replace using a dictionary     | <code>df['col'].replace({'US': 'USA'})</code> |
| Check for a word in text       | <code>df['col'].str.contains('word')</code>   |

```
df['name'] = df['name'].str.strip()
df['city'] = df['city'].str.title()
df['status'] = df['status'].str.lower()
```

### 4 Fixing Data Types

If a number column is saved as text, maths will not work on it. Fix data types early.

|                               |                                                        |
|-------------------------------|--------------------------------------------------------|
| Convert to number             | <code>pd.to_numeric(df['col'])</code>                  |
| Ignore errors when converting | <code>pd.to_numeric(df['col'], errors='coerce')</code> |
| Convert to date               | <code>pd.to_datetime(df['col'])</code>                 |
| Convert to text               | <code>df['col'].astype(str)</code>                     |
| Convert to integer            | <code>df['col'].astype(int)</code>                     |
| Check all column types        | <code>df.dtypes</code>                                 |

```
# Convert a date column
df['date'] = pd.to_datetime(df['date'])
df['year'] = df['date'].dt.year
```

### 6 Renaming and Dropping Columns

Clean column names make your code easier to read and your analysis easier to share.

|                         |                                                      |
|-------------------------|------------------------------------------------------|
| Rename one column       | <code>df.rename(columns={'old': 'new'})</code>       |
| Rename multiple columns | <code>df.rename(columns={'a': 'x', 'b': 'y'})</code> |
| Drop a column           | <code>df.drop(columns=['col'])</code>                |
| Drop multiple columns   | <code>df.drop(columns=['c1', 'c2'])</code>           |
| Drop a row by index     | <code>df.drop(index=0)</code>                        |
| Reset the row numbers   | <code>df.reset_index(drop=True)</code>               |

```
# Rename and drop in one flow
df = df.rename(columns={'Nm': 'Name'})
df = df.drop(columns=['unused_col'])
```

## 7 Spotting Outliers

Outliers are values that are way too high or too low. They can mislead your analysis.

|                            |                                                              |
|----------------------------|--------------------------------------------------------------|
| See min and max            | <code>df['col'].min() /<br/>df['col'].max()</code>           |
| Filter rows above a value  | <code>df[df['col'] &gt; 1000]</code>                         |
| Filter using percentile    | <code>df['col'].quantile(0.99)</code>                        |
| Remove extreme high values | <code>df[df['col'] &lt;<br/>df['col'].quantile(0.99)]</code> |
| Remove extreme low values  | <code>df[df['col'] &gt;<br/>df['col'].quantile(0.01)]</code> |

```
q_low = df['col'].quantile(0.01)
q_high = df['col'].quantile(0.99)
df = df[(df['col'] > q_low) &
(df['col'] < q_high)]
```

## 8 Saving Your Clean Data

Always save your cleaned dataset so you do not have to redo the work.

|                 |                                                              |
|-----------------|--------------------------------------------------------------|
| Save to CSV     | <code>df.to_csv('clean_data.csv',<br/>index=False)</code>    |
| Save to Excel   | <code>df.to_excel('clean_data.xlsx',<br/>index=False)</code> |
| Load CSV back   | <code>df =<br/>pd.read_csv('clean_data.csv')</code>          |
| Load Excel back | <code>df = pd.read_excel('clean_data.<br/>.xlsx')</code>     |

## Quick Checklist Before Analysis
